Aristotelion University of Thessaloniki,
Greece*

INTRODUCTION

GREECE, to those who know it only from archeological books and its ancient architecture, is associated with rocks, and bare mountains of white fine-granular marble, decorated by fine-sculptured Temples, all built of white marble. Probably, the small size pine-tree grove, ideally matched with scattered columnar cypress and olive trees, which not seldom constitute the frame that beautifies the ancient Greek landscape, do not prevent them from wondering whether Greeks, being in an arid country, had no choice in selecting their building material.

However, all over the Greek territory, the climate, characterised by more or less long dry and hot summers (typical mediterranean climate), is, in general, very favorable for the development of even dense forests.

No doubt, in prehistoric times Greece was totally covered with thick forests, with the only exception of the summits of high mountains, rising above the timber line.

The recently discovered bones, found in excavations near Pikerimi a few kilometers east of Athens, belong to a prehistoric large and very robust animal, the habitat of which is confined to extent forest environment. That gives a very strong evidence that Attica was covered by unbroken forests.

L. G. LIACOS

Greek Mythology, on the other hand, says that Hercules killed the Kithaeronian Lion and the Elk of Artemis (Diana) in Peloponessos. This allows to conclude that Peloponessos was covered with large forests, since lions and elk require a forest environment over large areas.

Moreover, Homer in his Odyssey calls the now bare mount Noriton in the island of Ithaca "denseleaved" (εἰνοσιφύλλον) and the island Zakynthos "forest covered" (ἰλήεσσα).

HISTORY OF BURNING

The destruction of the Greek forest largely began with the invasion of the country by various indogerman races. They started from the country around the Danube river, at the beginning of the 20th century B.C.

First, the Achains, a race purely nomadic, following the valley of the Axios river entered Greece, and arrived in Peloponessos through Central Macedonia, Thessaly, Biotia, and Attica. Using fire mainly, they converted large forested surfaces to grasslands, in order to secure better feeding for their numerous livestock animals, or to open passages to grass-covered lands (alpine rangelands).

Second, the Doreans, a mountainous race entered from Western Macedonia, and following the main mountain range went down as far as Peloponessos. They also converted large areas of forests to grasslands for the same reason, using the most effective tool, b u r n i n g.

Naturally started wildfires, also, were a very common phenomenon all over Greece. Homer in Iliad (Λ. 155) sings:

"Ὡς δ' ὅτε πῦρ αἴδηλον ἐν ἄξύλῳ ὕλη
πάντη τ' εἰληφῶν ἄνεμος φέρνει, οἱ δέ τε θάμνοι
πρόρριζοι πίπτουσιν ἐπειγόμενοι πυρός ὀρμῇ".

which means:

"And as when consuming fire falls upon thick woodlands and the whirling wind beareth it everywhither and the thickets fall utterly as they are assailed by the onrush at the fire."

Thoukidides, also, talking about the unexpected escape of Plataeans, while they were besieged by Spartans the summer of the third year of Peloponnesian war (429 B.C.), thanks to an unusual storm that followed a big fire the Spartans put all around the city, says:

"Καί ἐγένετο φλόξ τοσαύτη ὅσην οὐδεὶς πω ἔς γε ἐκεῖνον τόν χρόνον χειροποίητον εἶδεν· ἤδη γάρ ἐν ἄρεσιν ὕλη τριφθεῖσα ὑπ' ἀνέμων πρὸς αὐτήν ἀπὸ ταυτομάτου πῦρ καὶ φλόγα ἀπ' αὐτοῦ ἀνῆκεν. τοῦτο δέ μέγα τε ἦν".

which means:

"And a conflagration arose greater than any one had ever seen up to that time, kindled, I mean, by the hand of man; for in times past in the mountains when dry branches have been rubbed against each other a forest has caught fire spontaneously therefrom and produced a conflagration."

Forbes, also, talking about the importance of fire in ancient technology, says that ancient man applied burning "to extend the forest fires to manure the cleared spaces."

Therefore, burning has greatly contributed to the present physiognomy of the vegetation cover and the whole ecosystem of Greece, not only as a tool in hands of economy making man, but as an important factor of the natural environment too.

It is rather certain that "*Maquis*" and "*Garrigues*" formations (see Fig. 1), occupying at present about 15 percent of the total land area of Greece, is mainly a result of wildfires. Ch. Mouloupoulos⁴¹ says that the coastal zone of the Greek peninsula from Albania to Peloponessos and from Peloponessos to Chalkidiki was in previous times covered with productive forests of *Pinus halepensis*, *P. brutia*, *P. pinea*, and *Quercus ilex*, interrupted only by very dense *Fluviosilvae* and *Paludisilvae* around the mouth of big rivers—like the Axios river in Macedonia—or by deciduous oak forests growing in isolated stands. And, he states, that the main reason of their substitution by maquis formation was the wildfire, caused, mainly, by man to improve, primarily, grass and browse production, and secondarily to expand his cultivated land (Fig. 2).

L. G. LIACOS

FIG. 1. Maquis formation in Chalkidiki peninsula.

FIG. 2. Gradual substitution of *Pinus Halepensis* by maquis in Chalkidiki peninsula.

But ancient Greeks very early had seen that burning had also some beneficial effects.

Homer in Iliad (φ. 12), talking about the retreat of Argites after they lost the battle, and trying to escape, says:

"ὄρε δ' ὄθ' ὑπὸ ριπῆς πυρός ἀκρίδες ἠερέθονται
φευγέμεναι ποταμόνδε· τὸ δέ φλέγει ἀνάματον πῦρ
ὄρμενον ἔξαιφνης, ταί δέ πτώσσουσι καθ' ὕδαρ".

That means:

"And as when beneath the onrush of fire locusts take wing to flee on to a river and the unwearied fire burneth them with its sudden oncoming and they shrink down into the water."

Virgil, also, in his Georgics (book I, 84–93) says:

"Often, too, it has been useful to fire barren fields, and burn the light stubble in crackling flames; whether it be that the earth derives thence hidden strength and rich nutriment, or that in the flame every taint is baked out and the useless moisture sweats from it, or that heat opens fresh paths and loosens hidden pores, by which the sap may reach the tender blades, or that it rather hardens the soil and narrows the gaping veins, that so the searching showers may not harm, or the blazing sun's fierce tyranny wither it, or North wind's piercing cold."

Kassianos Vassus, too, refers to burning and its beneficial effects upon the crops, and says in his "Geoponica":

"Βελτίων κόπρος πάντων τοῖς λαχάνοις τέφρα, λεπτοτάτη γάρ οὔσα, καί φύσει θερμή, ἀποκτενεῖ τὰς ψύλλας καί τοὺς σκόληκας, καί τὰ τοιαῦτα θηρία". (book IB, 4-1)

which means:

"The best manure of all for vegetables is ash, and being most fine and naturally warm, it will kill the fleas and worms and other small beasts"

and also:

L. G. LIACOS

"τινές δέ αντί τοῦ νίτρου τῆ τέφρα χρώνται, καί διά τὰς κάμπας ἀνελεῖν". (book IB 17-1).

That means:

"some people use instead of nitre ash to also kill caterpillars."

and further (book IF, 10-1):

"Ἐάν μύρμηκας θηρόσας καύσης ἀποδιώξεις τοὺς λοιποὺς μύρμηκας, ὡς ἡ πεῦρα ἐδίδαξεν".

"If you hunt ants and burn them, you will expel all ants that are left, as experience has taught us."

Letsas³⁶ in his three volume *Mythology of Agriculture* reports that the ancients used to burn the stubble or the herbage and dry leaves to manure the fields. In Xenophon's *Economics* (XV III, 2) the famous Greek historian reports:

"Τό δ' ἐν τῇ γῆ ληρθέν (τῶν καλάμων) ἠγοῦμαι καί κατακαυθέν συναφελεῖ ἄν τήν γῆν καί εἰς κόπρον συμπληθύνειν".

"I imagine that the stubble may be burnt with advantage to the land, or thrown on the nature heap to increase its bulk."

PRESENT STATUS OF BURNING

At present, fire still constitutes a very important factor of the Greek wildland ecosystems. Wildfires in forests and rangelands are very common.

D. Kailidis²⁸ reports that from 1956 to 1971 the average number of wildfires registered all over Greece per year amounted to 612, and had destroyed, on average, 10.150 ha of forest and brushlands, with an estimated damage of about \$7,336,000. This represents 0.14 percent of the total forests and brushlands of Greece. More than 60 percent of the total burnt area is coniferous forest of *Pinus halepensis* and *P. brutia* of the lower Mediterranean zone, and maquis and garrigues formations. The surface burnt and losses from wildfires would be much greater, if forests in this zone were not broken in relatively small size stands by the interval of non-forested land.

PRESENT STUDIES AND HISTORY OF BURNING IN GREECE

The author, also, reports that in more than 60 percent of the fires the cause was carelessness (cigarettes), or inadequate control of stubble burning in neighboring wheat fields, that spread the fire over to forest ground fuel (ground fuel in *P. halepensis* and *P. brutia* forests is very flammable) or brushlands (Fig. 3).

D. Kailidis and A. Papagiannopoulos²⁷ studying the litter moisture trend under *Pinus brutia* stands and in openings in the Forest Park of Thessaloniki-city, found that from June to October in 1968, and from May to November in 1969, litter moisture content was less than 25 percent; this marks the critical point under which fuel burns very easily. In openings the accumulated grass litter had a moisture content even lower than that of pine-needle litter under the stands.

Generally, *Pinus halepensis* and *P. brutia* forests in Greece form relatively open stands, under the canopy of which grows a luxurious understory vegetation of evergreen, mainly, brush species and associated herbaceous plants, which dry-out during the summer months (Fig. 4).

FIG. 3. Wheatfields neighboring to brushlands may spread the fire when stubble burning is inadequately controlled.

This understory vegetation, intercepting in addition through all its depth the falling dead pine-needles is very flammable. This creates a big fire hazard. The fire hazard is particularly high in *Pinus halepensis* forests, managed primarily for gum production. Gummed pine-tree trunks with their wounds all around and gum droppings are very easy to burn, for they rapidly conduct the fire to the tree crown and to the forest canopy, in general, once started on the ground (Fig. 5).

Needless to say that with increasing tourist traffic and the mass outings of urban people from the noisy, airpolluted cities for outdoor recreation, fire danger is going to become great.

Brushlands, also, suffer big losses from wildfires every year. During the long rainless and hot summers the moisture content of their aerial part drops considerably, and it takes just a spark to start burning. Liacos and Mouloupoulos³⁷ report that moisture content of the browse—the most tender succulent tissues of the aerial part—produced by one of the main species of maquis formation, the Kermes oak (*Quercus coccifera*), drops down to about 40 percent in late summer. Certainly, the moisture content of the woody parts of the species, which constitute the bulk of fuel matter, is at that time much lower.

Burning is also used at present as a management tool. Wheat farmers almost all over Greece consider stubble burning a good technique for increasing wheat production. Livestock operators also in many districts use burning for range improvement. They practice it because they strongly believe in its beneficial effects, in spite of the general belief that burning is harmful, especially to the soil.

Farmers, have seen that when stubble burning is practiced in autumn or in winter time, crops are better the following season than when no burning is applied. They specifically observed the following after burning:

1. Plowing of the field and soil preparation for reseeding is much easier and perfect, that secures better germination of seeds and better development of the seedlings.
2. Wheat seedlings show no chlorotic phenomena in spring, as is the case when stubble burning is not applied.

PRESENT STUDIES AND HISTORY OF BURNING IN GREECE

FIG. 4. *Pinus brutia* stand with dense understory vegetation.

FIG. 5. *Pinus halepensis* stand used for gum production in the peninsula of Chalkidiki.

L. G. LIACOS

3. The season following stubble burning insect and disease attacks are less, and consequently crop damage reduced to a minimum.

4. Weeds are less abundant the season after stubble burning.

Agronomists are not in a position yet to give a definite and dependable answer to the problem. They experiment now on the various aspects of the problem.

Livestock operators, on the other hand, of Thesprotia County (Northwestern corner of Greece) use burning in low elevation rangelands every 4 or 5 years to control undesirable invaders and weeds. Weeds dominate in plant cover by the end of the 4th or 5th years after burning. It must be noted, here, that grazing in the area is practiced by sheep herders without any range management principle, and without any control as to the number of animals, the grazing period etc.

Livestock operators have seen that burning of dry range vegetation late in summer:

1. Secures a satisfactory control of weeds and other undesirable plants.

2. Stimulates a growth of dormant plants and provides green forage although in small quantities, when vegetation is completely dry.

3. Secures a relatively higher quantity of forage (grazable) for at least the next 2 years.

This technique of burning has been authorized even by the responsible state agency, the Greek Forest Service, under the pressure of the livestock operators, who live at present in this area as semi-nomads. However, the plant cover and especially the soil have been deteriorated to a high degree. A backward trend of the range condition is evident. The very valuable grass species *Andropogon distachyon* is greatly decreasing in vigor and density, and the invasion of the range by a Phrygana plant community (*Cystus* spp. etc) is obvious.

Certainly, livestock people do not realize that burning alone, without the application of a rational and proper plan for the specific area management-use and improvement, not only fails to have the expected results, but besides it becomes the main cause of heavy

PRESENT STUDIES AND HISTORY OF BURNING IN GREECE

degradation of the main resources of the range ecosystem, namely the *V e g e t a t i o n* and the *S o i l* (Fig. 6).

Livestock operators also use burning, although without permission, for improving browse production in brushlands. Here again burning is practiced not properly and not prescribed by a management working plan, with the result, finally, of a more or less severe degradation of the vegetation cover and the soil (Fig. 7).

PRESENT STUDIES OF BURNING

Fire, as it is easily concluded from the preceding analysis, continues to be an important factor even in the modified now wildland ecosystem, that dominates, particularly, in the lower Mediterranean zone of Greece.

Moreover, all activities developed today for restoration of the wildland vegetation and the reestablishment of the forest primarily for protection and recreation purposes (environmental forests), magnify the importance of the fire factor and render it, I might say, dominant in the environmental forest ecosystem, under, especially, the rapidly increasing tourist traffic and the demand for outdoor recreation.

Upon the basis of these facts and considerations lie our studies on prescribed burning, inspired and guided by the relative research and application work done in the U.S.A.

We thought that burning might be a very valuable tool, and an unsubstituted servant in the management of Greece's wildlands, if properly used and manipulated with understanding.

After a thorough analysis of the problem, it was concluded that prescribed burning might be indicated and valuable in management of the following three distinctive ecosystems:

- A. In the coniferous forests of *Pinus halepensis* and *Pinus brutia*.
- B. In the *Maquis* formation.
- C. In the high mountain grasslands, dominated by hard bunch-grasses.

The specific problems in each of these three ecosystems, and the

L. G. LIACOS

FIG. 6. Degradation of burnt rangelands in Thesprotia County is evident.

FIG. 7. Progressive degradation of brush vegetation (maquis) and soil because of unwise burning and uncontrolled grazing.

experimental work planned and undertaken are presented in the following discussion.

CONIFEROUS FORESTS

In the coniferous forests of Aleppo or Brutia pine, naturally existing or artificially created in their natural area by reforestation, two main categories of stands can be distinguished.

A. Forests on good site.

Growth conditions allow here the development or the creation and maintenance of thick stands during at least the first half of their rotation time.

With the progress in age of the stand one can see:

1. A number of trees dieing-off under the effect of the severe competition developed among trees (natural thinning) having no commercial value, and thus representing an actual loss for the forest business. For the same reason all understory vegetation is gradually dying-out too (Fig. 8).
2. A continuous increase of dead branches of living trees remaining in place, decreasing thus the quality, and consequently the value of the timber produced, even if after several years that they may be broken, but always in a considerable distance from the tree-trunks (Figs. 9 and 10). Under Mediterranean climate, and particularly in its lower part, natural pruning, that constitutes in classical silviculture one of the reasons justifying thick stands, seems to be an empty word. Decomposers, the main agent in natural pruning, can not be very active, because moisture is insufficient when temperatures are sufficiently high in summer time.
3. An accumulation on the ground of pine needles in thick undecomposed layers, and a storage of dead pine needles upon the dead branches of trees or upon understory woody vegetation (Figs. 11 and 12). The decomposition of the litter is very, very slow for the same reason mentioned above.
4. A large volume of slash left upon the ground after each thinning of the stands, once the diametre of the trees reaches commercial value.

L. G. LIACOS

FIG. 8. *Pinus halepensis* stand about 30 years old. Dominated trees and under-story brush dying-off under the effect of competition.

FIG. 9. Dead branches remaining in place in an artificially established stand of *Pinus brutia* 30 years old.

PRESENT STUDIES AND HISTORY OF BURNING IN GREECE

FIG. 10. Artificial stand of *Pinus brutia* about 35 years old immediately after the first thinning. Notice the broken dead branches in distance from trunks.

FIG. 11. Close-up view of accumulated pine-needle litter under a 30-year stand of *Pinus brutia*.

FIG. 12. Artificial stand of *Pinus brutia* 30 years old with thick layers of undecomposed needles on the ground and upon dead branches.

5. In the older stage during the second half of the rotation time the stands are thinned naturally, for they are constituted by light tolerant (light demanding we might say better) species. The density of the stands is decreasing as they approach the end of the rotation time. Under such relatively open stands a dense understory of woody and herbaceous vegetation grows (Figs. 5, 15), which in summer time is very flammable; its moisture content is then very low. This is one of the reasons for which *P. halepensis* and *P. brutia* stands are not thinned properly in early age stages with the result of a lower value of timber produced.
6. After the final cut of the stand at the end of the rotation time the understory vegetation grows extremely vigorous and dense in absence of any competition from pine trees. Under such conditions natural regeneration becomes uncertain, or it completely fails. On the other hand, artificial regeneration can be warranted only with high cost.

B. Forests on poor site.

Here the stands grow more or less open from a very young age. Under such stands an understory brush and/or herbaceous vegetation is developed, and a heavy flammable fuel is stored on the ground, much the same way as that under aged stands growing on good sites, creating similar problems from the very beginning in each stand.

It is certainly clear after this brief analysis that the fire hazard in such coniferous forests of the lower Mediterranean climate is very big.

Obviously, the elimination of the accumulated on the ground highly flammable fuel, and furthermore the prevention of accumulation of new fuel on the forest floor is of paramount importance.

One way to do this is to take away from the forest any flammable matter every-time its quantity exceeds the security limits. However, this creates heavy expenses, increasing, finally, very much the cost of the timber and/or gum produced, and the offered services of protection, recreation and landscape improvement as well.

Certainly, prescribed burning might be a suitable and extremely valuable tool, and a very good solution of the problem, under conditions we knew whether, how, when and where this technique could be applied in Greece. And furthermore, if following prescribed burning the establishment and maintenance of an understory vegetation of forage plants could be easy, then the practice of a proper grazing by livestock and/or wildlife animals could not only prevent the accumulation of fuel under the forest canopy, but it would, in addition, produce a considerable income instead of expenses. Besides, this would minimize the competition of the understory vegetation with trees, as far as soil moisture is concerned that constitutes the main limiting factor of plant growth in the Mediterranean zone, and thus greatly benefit the forest and consequently timber production. This would, perhaps, also encourage silviculturists to thin properly the stands for maximizing the value of the timber that can be produced in proportion to site potential, since they would not be annoyed by an undesirable understory vegetation. In addition, once the understory vegetation could be easily controlled even with benefit (grazing), the application of

L. G. LIACOS

fertilizers for further increase of timber and forage production would be possible and economically justified.

With this in mind as the basic hypothesis, and in view of the facts and the experience gained in the U.S.A., a number of experiments were planned and have been put under way since 1968 in *Pinus brutia* stands; namely:

1. In artificial stands, 30 years old.
This experiment was established in 1968 near Serrai-city at 650 m above sea level. There are applied three treatments:
 - (a) No treatment (Fig. 12)
 - (b) Artificial pruning, conservative thinnings (Fig. 14)
 - (c) Artificial pruning, intense thinnings, prescribed burning, seeding of forage plants for grazing (Fig. 14).
2. In natural stands of about 70 years old.
This experiment has been established in island Thassos at 10 m. above sea level. Two treatments are applied and compared here:
 - (a) No treatment (Fig. 15)
 - (b) Artificial pruning, intense thinning, seeding forage grasses for grazing (Figs. 16 and 17)
3. In artificially created stands by planting nursery plants of 1 year old on grass-covered soil in three densities (2×2 , 3×3 and 4×4 m.) This has been established in Sedes near Thessaloniki (elevation 50m.) in 1971. Two treatments are going to be compared here in each density:
 - (a) Conservative thinnings only.
 - (b) Intense thinnings in proper time, grazing of forage vegetation, prescribed burning when needed.
4. In artificially created stands by planting nursery plants of 1 year old on forest soil, after the natural stand of 70 years old with dense brush understory vegetation was burnt by wildfire, in two densities (3×3 and 4×4 m.) This has been established in island Thassos (elevation 150 m.) in 1971, and there will be applied for comparison two treatments:
 - (a) Conservative thinnings only.
 - (b) Intense thinnings in proper time, grazing, prescribed burning when needed and indicated.

PRESENT STUDIES AND HISTORY OF BURNING IN GREECE

FIG. 13. *Pinus brutia* stand 30 years old under conservative silvicultural treatment.

L. G. LIACOS

FIG. 15. *Pinus brutia* natural stand 75 years old with heavy understory vegetation of evergreen brush species.

FIG. 16. The same stand of Figure 15, viewed from another point, 1 year after prescribed burning, with the forest supervisor of Island Thassos wondering.

FIG. 17. The same stand of Figure 15 2 years after prescribed burning. A second burning is planned for winter 1973-74.

Two more experiments have been planned and will be established next fall, one in artificial stands, 15 years old, in Chalkidiki at 400m. above sea level, and a second one in stands of different densities (2×2 , 3×3 and 4×4 m.) that are going to be created by planting nursery plants on brushlands after and no burning the brush-cover.

A similar research work is planned for the *Pinus halepensis* forests, that it is hoped to start soon. Meanwhile, a trial of burning was made in natural stands, 30 and 60 years old, that orients our work to be undertaken (Figs. 18, 19 and 20).

With this net of experiments it is hoped and expected to have valuable results, that properly analysed and interpreted, would answer the general problems created by the use of prescribed burning in forests of *Pinus halepensis* and *Pinus brutia*. More specifically it is expected to answer the questions which came out of the analysis of the problem made above, that constitute the general hypothesis of the study.

L. G. LIACOS

FIG. 19. The same stand of Figure 18 (from another photo point) while burning the understory vegetation and the slash after intense thinning.

FIG. 20. The same stand of Figure 19 after burning.

UP TO DATE RESULTS

Although it is very early to have valuable conclusions, a number of data and observations could be of interest. The results of the compiled up-to-date data are as follows:

1. It is rather certain that *Pinus halepensis* and *Pinus brutia* endure quite well, prescribed burning of brush understory vegetation at an age of 30 years and thereafter. Their Rhytidome is at that age thick enough to protect the cambium from the released heat (Fig. 21).

2. The temperature of mineral soil under burnt brush and slash is hardly affected, when burning is applied in winter 2 or 3 days after a rain good enough to soak well under the litter humus. Measurements made showed 15°C. after fire ran over it, while air temperature was 16°C. Thus soil was not affected at all.

3. Soil nitrogen was found to be higher in burnt than in unburnt plot the first year after burning. It was 0.189 percent and 0.126 percent respectively.

4. The establishment of seeded orchardgrass (*Dactylis glomerata*)

FIG. 21. Rhytidome of *Pinus brutia* 30 years old. One can see the decrease in growth after the 15th year because of the high density of the stand. Thinnings should begin 10 years earlier at least.

—after burning in intensively thinned plot was satisfactory. Volunteers, among which were many legumes, colonised the soil after burning in satisfactory degree. Main volunteers: *Festuca ovina*, *Aristella bromides*, *Andropogon ischaemum*, *Koeleria cristata*, *Phleum* spp. *Trifolium purpurem*, *Trifolium angustifolium*, *Trifolium arvense*, *Vicia* spp. *Poterium sanguisorba*.

5. In burnt plot, after three consecutive thinnings of the 30 year old stand, that lowered the tree number per hectare from 1100 to 450, total volume (standing and taken by thinnings) was equal to that of the plot treated according to conservative silvicultural rules. (see Table 1 and Fig. 22). Also the increment of standing trees after thinning was much higher in the intensively thinned and burnt plot (Fig. 23).

6. Pine regeneration 2 years after last burning was very good. In the unburnt plots many seedlings were found from germinated seed

PRESENT STUDIES AND HISTORY OF BURNING IN GREECE

during past fall, but almost none from germinated seeds in previous years. Table 2 shows the pine seedlings found in February 1973 in burnt and unburnt plots.

TABLE 1

Treatments	Volume in 1968	Volume of thinnings	Volume in 1972	Total Volume	Increments o/o
Intensive thinning—Prescribed burning	20.53	12.99	12.36	25.35	23.47
Conservative thinning.	19.34	1.52	21.56	23.08	19.33
Control	17.93	—	18.76	18.76	4.62

TABLE 2

Treatments	Intensive thinning—Prescribed burning plot	Conservative thinning plot	Control plot
Seedlings less than 1 year old	2	17	23
Seedlings older than 1 year	15	—	—

EVERGREEN BRUSHLANDS

Maquis brushlands are now used by browsing animals such as goats and deer mainly. Their value as browse-land is not very high. Liacos and Mouloupoulos³⁷ found that browse production of this land in good condition does not exceed for the area studied, 750 kg/ha air dry. Liacos³⁸ in a conversion study from brushland to grass by seeding *Dactylis glomerata*, *Phalaris tuberosa* and *Trifolium hirtum* after mechanical clearing of brush, found that grass forage production was about 500 kg/ha airdry.

With this in mind and the fact that wildfire hazard is very high

FIG. 22. Volume of standing and thinned-out trees in *Pinus brutia* plots: A. Intensively thinned and burnt. B. Lightly thinned. C. Control.

FIG. 23. Increase of diameter in dbh of *Pinus brutia* trees in plots: A. Under intensive thinning and burning. B. Under light thinning. C. Control.

PRESENT STUDIES AND HISTORY OF BURNING IN GREECE

in this vegetation type a comparative research study was started last year. Prescribed burning is used as the main tool of conversion, followed by planting of a mixture of seeds of *Lolium multiflorum* (used as the main competitor against brush sprouts), *Dactylis glomerata*, *Phalaris tuberosa* and *Trifolium hirtum*. On the other hand, brush vegetation in the remaining underbrush covered plots is improved by proper manipulation of brush individuals and the whole community as well, for reaching maximum browse production (Fig. 24).

The purpose of this experiment is to find out:

- (a) Whether brush conversion by prescribed burning constitutes an efficient technique.
- (b) How to control brush sprouts after burning.
- (c) What is the production of forage as compared to browse produced.
- (d) Which is the technique to follow in order to insure a good establishment and maintenance of forage cover.

FIG. 24. Brush vegetation treated for high browse production.

L. G. LIACOS

HIGH MOUNTAIN GRASSLANDS

Prescribed burning has been also used in a research study to improve forage production of high mountain rangelands, dominated by hard bunch-grasses, grazed for centuries only by sheep and goats.

Large quantities of undecomposed litter on the ground surface prevent the seedlings from rooting into the mineral soil, and are easily and regularly uprooted by grazing sheep.

The experiment has been established at an elevation of 100 m in the fall of 1971 in mount Phalacron (bold) in Northern Greece, representing an area of more than 10.000 ha in this mountain and manyfold larger area all over Upland Greece.

Burning was applied in fall and in spring immediately after snow melt in combination with and without chemical fertilization (Fig. 25).

The first year results show that burning improved the quality of

FIG. 25. Experimental plot in high mountain bunch-grasslands. Fall and spring burning is checked in combination with and without mineral fertilization for forage improvement.

PRESENT STUDIES AND HISTORY OF BURNING IN GREECE

the forage; it was more tender and palatable. Its crude protein content was higher than in unburnt forage, while quantitatively no difference was found thus far.
